Managing Weeds in Lentils

In recent years there has been increased interest in diversifying Montana’s cropping systems through the inclusion of pulse crops such as peas, dry beans, chickpeas, and lentils. Pulse production provides several agronomic advantages and opportunities to increase profit margins. Besides tolerating drought conditions, cool temperatures, and a wide variety of soil types, leguminous pulse crops can also help fix nitrogen in the soil. However, growers should be aware of the challenges and opportunities of managing weeds in these crops.

Weed management in lentils is of particular importance as this crop is generally considered to be a poor competitor due to its slow establishment and limited vegetative growth. Yield loss from competition with weeds can range as high as 80 percent. Lentil’s low competitive ability is compounded when growing season temperatures are low or when moisture is scarce. Growers considering incorporating lentils into their rotation should develop an Integrated Weed Management plan that considers the entire crop lifecycle from pre-planting to after-harvest. In doing so, they need to take advantage of cultural, physical, and chemical practices to reduce the spread and impact of weeds invading lentil fields. In Montana, difficult to manage weeds in lentils include catchweed bedstraw, Canada thistle, Russian thistle, kochia, common lambsquarters, cow cockle, shepherds purse, henbit, Mayweed chamomile, wild buckwheat, prickly lettuce and dandelion. Of these, Canada thistle and catchweed bedstraw are particularly difficult to control and producers should avoid fields with a history of these species.

Cultural practices to decrease weed pressure in lentil crops include prevention, seedbed preparation, variety selection, proper sowing and crop establishment, insect and disease management, nutrition management, and irrigation scheduling. For example, Baird and collaborators (2009) observed that increasing the seeding density of lentils translated into increased yield and decreased weed biomass (Figure 2, page 2). However, while cultural practices are at the backbone of an integrated weed management plan, they alone may not be enough to secure adequate weed control in lentil fields. More information on cultural considerations and variety selection can be found in the Montguide, Growing Lentils in Montana (MT199615AG).

Mechanical weed control practices in lentils, such as harrowing or rotary hoeing fields after emergence, represent a viable alternative for organic producers. Producers should be aware that mechanical weed control practices should be applied with caution due to the high sensitivity of lentil shoots and roots to damage. If harrowing or hoeing is planned, be sure to increase seeding rates because...
mechanical damage may reduce stands. Also, producers should minimize the risk of soil erosion due to excessive reliance on tillage.

*Crop rotation* is one of the most powerful tools to manage pest problems. It is very important to carefully consider the crop rotation history prior to growing lentils as this crop is very sensitive to many herbicides used in small-grain production. The high persistence SU-herbicides commonly used in small grain crops such as Ally (metsulfuron), Glean (chlorsulfuron), and Finesse (chlorsulfuron) can damage subsequent annual legumes, including lentils. Due to their persistence, it may be necessary to wait up to four years before seeding lentils, depending on the product, application rate, and weather conditions.

The persistence of herbicides in the soil depends on many factors including soil pH, moisture, temperature, soil texture, and soil organic matter. Understanding the risk of crop injury due to soil applied herbicides is particularly important in areas with dry climate and prolonged winters, like Montana, where herbicides generally degrade slowly (Table 1, page 3).

*Chemical weed control* can help reduced-till or no-till lentil producers manage weeds. Research and experience has shown that herbicides are most effective when used as part of an IWM program. The applicability and success of herbicides in lentil fields depends on the cropping system, land preparation methods, soil conditions, and weed problems. For example, Sencor (metribuzin) applied at recommended rates provides effective weed control, but it can cause crop damage in stressful conditions of cold weather, low fertility, disease, or insect damage. Also, although Pursuit (imazethapyr) can be used to manage broadleaf weeds in no-till or minimum tillage systems, cold and wet conditions occurring within a week of application can severely damage the crop.

While information on commonly used herbicides used to manage weeds in lentils is provided below, producers should carefully read and follow product labels prior to using any herbicide.

---

**What is Integrated Weed Management?**

Integrated weed management (IWM) combines the use of biological, cultural, mechanical, and chemical practices to manage weeds, so that reliance on any one weed management technique is reduced. The main goals of an IWM program are to 1) use preventive tools to maintain weed density at a level that does not harm the crop, 2) prevent shifts toward more difficult to control weeds, and 3) develop agricultural systems that maintain or improve crop productivity, farm revenues, and environmental quality. Designing a successful IWM program requires understanding the different biological and ecological factors that influence the short-, mid-, and long-term dynamics of weeds in agricultural settings.

More information on IWM can be found in Montguides *Integrated Strategies for Managing Agricultural Weeds: Making Cropping Systems Less Susceptible to Weed Colonization and Establishment* (MT200601AG) and *Weed Seedbank Dynamics & Integrated Management of Agricultural Weeds* (MT200808AG).
- **Assure II** (quizalofop). 5 to 12 ounces/acre. Apply postemergence (POST) to manage annual and perennial grasses. Apply with crop oil concentrate (COC) or nonionic surfactant (NIS). Application intervals should be greater than seven days apart to allow re-growth. Do not apply within 60 days of harvest. Consult label for crop rotation restrictions.

- **Dual Magnum** (7.62 EC)/generic S-metolachlor products. 1 to 2 pints/acre. Apply Preplant Incorporated (PPI) or Preemergence (PRE). For annual grass and some broadleaf weed control. Does not control emerged weeds. Incorporation improves control. Refer to label for specific rate information regarding soil texture and OM. Use low rates on coarse soils with less than three percent organic matter (OM) and higher rates on fine soils with over three percent OM.

- **Far-Go** (triallate). 1.5 quarts/acre. PPI. Mostly used to manage wild oats. Apply up to three weeks before seeding or after seeding before sprouts are 0.25” long. Apply prior to wild oat germination. A two-pass incorporation is recommended. Do not rotate to crops other than winter wheat, spring wheat and durum, triticale, barley, peas, lentils, and sugar beets for 12 months after a Far-Go application. In Montana, do not use Far-Go on fields to be seeded to hard red spring wheat with press drills if the field is or will be irrigated in the current growing season.

- **Outlook/generic dimethenamid-p.** 10 to 16 ounces/acre. Apply pre-plant surface or PRE to lentils. Good to excellent control of several annual grasses. Fair to good control of certain annual broadleaf weeds such as pigweed, waterhemp, or black nightshade. Adjust rate for soil type and OM. Consult your seed dealer for restrictions on specific varieties to avoid potential injury due to sensitivity. Emerged weeds are not controlled. May occasionally result in temporary spotting or browning of crop leaves. Lentils may be harvested 70 days after application. Refer to label for tank-mix options.

- **Paraquat products.** Available in several brand name products including Gramoxone Inteon, Gramoxone Max, Firestorm, Parazone 3SL, and others. Follow specific label directions for product used. HARVEST

### TABLE 1. Lentil rotation interval for herbicides commonly used in Montana.

Consult your seed dealer for restrictions on specific varieties to avoid potential injury due to sensitivity. Emerged weeds are not controlled. May occasionally result in temporary spotting or browning of crop leaves. Lentils may be harvested 70 days after application. Refer to label for tank-mix options.

### Timing is Everything

To maximize the effectiveness of any weed management practice and avoid yield reduction, it is important to target the proper crop growth stage. Research conducted at the University of Saskatchewan, Canada, showed that weed control in lentils should start by the five- to six-node stage, and lentil fields should continue weed-free until the ten- to eleven-node stage. While the environmental conditions under which this study took place differ from the ones we experience in Montana, these results can help lentil growers time their weed management practice.
Preventing herbicide resistance

Herbicide resistance is the innate ability of a weed biotype to survive and reproduce after treatment with an herbicide dose that would normally be lethal. In Montana herbicide resistant biotypes of wild oat, Persian darnel, green foxtail, kochia, and Russian thistle have been found.

To reduce the risk of selecting for herbicide resistant biotypes, producers should rotate among herbicides with different modes of action applied either as tank mixes, premix formulations, or sequential applications. Also, producers should rotate management practices, such as the incorporation of timely cultivation. Finally, crop rotation is an excellent tool to reduce the selective pressure on herbicide resistant weeds. More information on herbicide resistance can be found in the Montguide, Preventing and Managing Herbicide-resistant Weeds in Montana (MT200506AG).

Reducing the risk of herbicide injury in lentil crops

Herbicides are valuable tools: they help to control weeds and, if they are residual, can provide season-long control. However, miscalculations in their use can cause crop injury or failure to control weeds. Montana producers know that losing a crop due to lack of rain is an unfortunate but inevitable experience. Losing a crop because of herbicide injury could be as bad as a weather calamity, but it can be prevented. Minimizing the risk of herbicide crop injury is a necessary step for diversifying dryland cropping systems in Montana to include broadleaf crops such as pea, lentil, canola and sunflower.

To minimize the risk of herbicide-injured crops, we need to understand how herbicides function and the several factors that affect their activity. For example, the soils of Montana are unique in that they have lower organic matter and higher pH than is typically encountered outside this region. Also, many times Montana’s soils are different than those where herbicide residue studies have been conducted and upon which current recommendations are based.

For the last 3 years, researchers and graduate students at Montana State University have been evaluating the potential damage that herbicides could cause in crops. To determine the best way to maximize the benefits of herbicides while avoiding crop injury we have assessed carryover effects on different crops and soil types across Montana. This information is available at the Cropland...
Managing weeds in herbicide-tolerant lentils

Lentil producers can take advantage of the Clearfield system to manage tough weeds. The Clearfield system combines herbicide-tolerant (non-GMO) lentil varieties with Beyond herbicide (imazamox). Beyond is a broad-spectrum post-emergence herbicide that provides post-emergence and in-season residual weed control of several annual broadleaf weeds such as chickweed, shepherd’s-purse, field pennycress, common lambsquarters, pigweed and wild buckwheat. It also provides control of several grasses including jointed goatgrass, feral rye, downy brome, Japanese brome, cheat, Italian ryegrass, wild oats and volunteer cereals.

Preventing the selection and spread of herbicide-resistant weed biotypes is a challenge to the Clearfield technology. Beyond inhibits the activity of the acetolactate synthase (ALS) enzyme, the first step in the biosynthesis of the branched chain amino acids valine, leucine and isoleucine. The lack of these amino acids restricts the building of proteins and results in the slow death of treated plants. ALS inhibiting herbicides have been used in crop production since the 1980’s. Unfortunately, the likelihood of selecting resistant weed biotypes with the continuous use of this class of herbicides is very high.

Weed management at harvest

Many times after a cool and wet summer, weeds keep on growing and lentils continue flowering and setting pods. These conditions mechanically impair the harvest of the crop, and herbicides can aid lentil growers in harvesting crops. Some of the advantages of a pre-harvest herbicide application include facilitating direct combining of standing crops, managing in-crop weed escapes, reducing dockage, and controlling perennial weeds in subsequent crops.

Lentil growers must carefully ponder the management goal, the weeds present, and the crop seed maturity stage prior to applying a preharvest herbicide as these variables will affect the herbicide choice. There are two common choices for an in-crop, pre-harvest herbicide: Roundup (or other generic glyphosate) and paraquat. A pre-harvest application of glyphosate provides adequate weed control including winter annual and perennial weeds, but the crop will be slow to dry down. Glyphosate should not be applied to lentils grown for seed production as germination and possibly vigor problems may occur in the spring. Paraquat is a true desiccant herbicide that should be used when the main goal is to desiccate the crop (Table 2). Remember that herbicide use will not speed up crop seed maturity.

How to conduct a field bioassay

Field bioassays allow producers to evaluate the risk of crop damage due to herbicide carryover. Using typical management practices (tillage, seeding depth, timing for the particular crop, etc.) plant several strips of the desired crop variety across the field which has been previously treated with the suspected herbicide as well as areas that have not been treated with the herbicide. Plant the strips perpendicular to the direction the herbicide was applied. Place these strips to capture field heterogeneity due to differences in soil pH, texture, organic matter, and drainage. Using the untreated areas as a control, check the crop for visible symptoms of injury, stand reduction, and/or yield reduction. If no herbicide injury symptoms or yield reduction is visible, the field can be seeded with this crop the next growing season after the bioassay. However, if visible herbicide injury symptoms or yield reduction occur, this crop must not be seeded, and the bioassay must be repeated the next growing season.

Glossary

Ammonium sulfate (AMS) is an additive recommended by many herbicide labels. AMS often improves weed control, especially when mixed with hard water.

Crop oil concentrate (COC) is comprised of a non-phytotoxic (not causing injury) mineral and/or vegetable oil and can contain up to 20 percent surfactant. The principal function of the COC is to aid in moving the herbicide across the leaf cuticle and reduce the surface tension of the spray droplets. Crop oils are also effective at increasing spray retention on leaf surfaces and reducing drying times, allowing more time for the herbicide to penetrate the leaf.

Genetically modified organism (GMO) or genetically engineered organism (GEO) is an organism whose genetic material has been modified through the use of genetic engineering techniques. Genetic engineering combines DNA molecules from different sources to create a new set of genes. This new molecule is then transferred into an organism, giving it modified or novel genes.

Nonionic surfactants (NIS) are specialized additives formulated to improve the performance of herbicides in spray solution. The function of the NIS is to spread the spray droplet evenly over the leaf surface, help it to adhere to the leaf, and increase penetration of the herbicide within the spray droplet into the waxy cuticle that covers the leaf surface.

Sulfonylurea (SU)-herbicides are a family of herbicides discovered in 1975 and widely used in Montana. SU herbicides work by inhibiting a key enzyme — acetolactate synthase — which is unique to plants (not present in humans, animals, insects, birds or fish) and is needed for plant growth. Examples of SU herbicides include Maverick (sulfsulfuron), Glean, Finesse and Ally.
